Using the WMAP cosmic microwave background data it is shown that collisions between Alfvén wave packets and the cascades generated by these collisions (the Iroshnikov model) can determine the photon temperature fluctuations for arcminute scales on the last scattering surface.

PACS numbers: 52.40.Db, 98.80.Cq, 98.70.Vc

Cosmic electromagnetic fields are expected to be generated by the cosmological phase transitions (electroweak and QCD) in a wide interval of scales [1, 15] before the recombination time. At earliest times, the magnetic fields are generated by particle physics processes, with length scales typical of particle physics. It is shown in [1] that rotational velocity perturbations, induced by a tangled magnetic field, can produce significant angular scale anisotropies in cosmic microwave background (CMB) radiation through the Doppler effect. The conclusions are relevant to arcminute scales [3, 4, 6]. In particular, it is shown in [3, 4, 6] that rotational velocity perturbations on the last scattering surface [3, 4, 6, 17]) are effectively dissipated on these scales (it is known [4] that on the last scattering surface typical magnetic fields to propagate [16]. Magnetohydrodynamic (MHD) turbulence is characterized by a competition of two processes, Alfvén wave packets collisions and swirling motions. It is known [3] that on the last scattering surface the nonlinear Alfvén wave mode survives photon (Silk) damping on the arcminute scales, while the general swirling motions (as well as the compressional modes) are effectively dissipated on these scales (it is significant for further consideration that the Alfvén wave modes induce specific rotational velocity perturbations on the last scattering surface [3, 4, 6, 16, 17]). Therefore, the cosmic baryon-photon fluid becomes dominated by Alfvén waves on the arcminute scales just before the recombination time. In the present paper we will show that specific statistical properties of such Alfvén wave dominated fluctuations are consistent with the new (WMAP) arcminute CMB data.

The incompressible magnetohydrodynamic equations can be written in terms of the Els"asser variables

$$\mathbf{z}^\pm = \mathbf{v} \pm \mathbf{B}$$

as

$$\partial_t \mathbf{z}^\pm + \nabla \mathbf{v}^\mp \cdot \nabla \mathbf{z}^\pm = -\nabla P + \nu_+ \Delta \mathbf{z}^\pm + \nu_- \Delta \mathbf{z}^\mp,$$  

(2)

where $\nu_+ = \frac{1}{2}(\nu + \eta)$, $\nu_- = \frac{1}{2}(\nu - \eta)$, $P$ is the total pressure, $\nu$ and $\eta$ are coefficients of hydro and magnetic diffusion respectively. The equations are given in convenient nondimensional form using units $B/B_0 \rightarrow B$, $u/u_0 \rightarrow u$, $u_0 = B_0/(4\pi p)^{1/2}$ and $B_0$ is a typical magnetic field intensity.

Scaling of the structure functions of the Els"asser variables

$$\langle |\mathbf{z}^\pm(\mathbf{x} + \mathbf{r}) - \mathbf{z}^\pm(\mathbf{x})|^p \rangle \sim r^{\zeta_p}$$  

(3)

is used as an effective tool to study their dynamics.

A first attempt to describe magnetic turbulence dominated by Alfvén waves was made in [10]. In the incompressible fluid, any magnetic perturbation propagates along the magnetic field line. Since wave packets are moving along the magnetic field line, there are two possible directions for propagation. If all the wave packets are moving in one direction, then they are stable. Therefore, the energy cascade occurs only when the opposite-travelling wave packets collide, and only collisions between similar size packets are taken into account in the Iroshnikov model. The following amount of energy: $\Delta E \sim (v_0^2/l)(1/V_A)$ is released at collision of the two wave packets of the same size $l$. The energy change per collision and the duration of the collision are respectively $v_0^2/(V_A/l)$ and $\Delta t \sim l/V_A$, where $V_A$ is the Alfvén speed. Total number of collisions for the cascade can be estimated as $v^2/\Delta E$. Hence, the energy cascade time $\tau_l$ is

$$\tau_l \sim (v^2/\Delta E)^2 \Delta t \sim \frac{l}{v_0^2/\Delta E},$$  

(4)

That is the cascade time is $(V_A/v_0)$ times longer than the eddy turnover time $(l/v_0)$. The constancy of energycascade, $(v_0^2/(IL_A) = constant$, is assumed in the model, which results in

$$v_0^4 \sim l.$$  

(5)

It then follows from (4) and (5)

$$\tau_l \sim t^{1/2}.$$  

(6)

There exists a general representation for $\zeta_p$ [3]  

$$\zeta_p = p/g(1-x) + C_0[1 - (1 - x/C_0)^p/g],$$

(7)
where \( g \) is related to the basic scaling \( \delta v_0 \sim t^{1/g} \) (in the Iroshnikov model (5) gives \( g = 4 \)), \( x \) is the scaling of dynamic time scale of the most intermittent structures, \( \tau_1 \sim t^x \) (in the Iroshnikov model (6) gives \( x = 1/2 \)), \( C_0 \) is the co-dimension of these structures with the spatial dimension \( d \); \( C_0 = 3 - d \) (in the Iroshnikov model these structures are known to be micro-sheets, i.e. \( d = 2 \) and, consequently, \( C_0 = 1 \)). Then, for the Alfven wave dominated model \( \zeta_4 = 1 \) (cf. basic scaling (5)). Using this fact, the so-called extended self-similarity (ESS) can be introduced in the form \( \zeta_p = \frac{p}{2} + 1 - (1/2)^{p/4} \). (7)

It is very significant that for this model \( \zeta_4 = 1 \) (cf. basic scaling (5)). Using this fact, the so-called extended self-similarity (ESS) can be introduced in the form \( \zeta_p = \frac{p}{2} + 1 - (1/2)^{p/4} \).

The remarkable property of the ESS is that the multiscaling (8) can survive even if the original multiscaling (3) does not exist. Due to the local (small-scale) isotropy of the fluctuations in the model we suppose that the ESS has the same \( \zeta_p \) for any vector component of the space difference: \( \vec{z}^\pm(x+r) - \vec{z}^\pm(x) \).

We use the ESS and the model (7) to check whether the cosmic microwave background (CMB) data, obtained recently by the WMAP space mission, support the Alfven wave domination on the arcminute scales (cf Introduction). For this purpose we calculated moments \( \langle \Delta T^p \rangle \), the space differences of the CMB temperature fluctuations \( \Delta T_r = |T(x+r) - T(x)| \), and then checked the multiscaling

\[ \langle \Delta T^p \rangle \sim \langle \Delta T^4 \rangle^\frac{p}{4}, \]

(cf. (8)).

The motion of the scatterers imprints a temperature fluctuation, \( \delta T \), on the CMB through the Doppler effect \( \delta T = g(L)n \cdot v_b(x) \, dL \) (see also \( \delta T = g(L)n \cdot v_b(x) \, dL \)).

where \( n \) is the direction (the unit vector) on the sky, \( v_b \) is the velocity field of the baryons evaluated along the line of sight, \( x = L n \), and \( g \) is the so-called visibility. It should be noted that, in a potential flow, waves perpendicular to the line of sight lack a velocity component parallel to the line of sight; consequently, generally there is no Doppler effect for the potential flows. The same is not true for vortical flows, since the waves that run perpendicular to the line of sight have velocities parallel to the line of sight (see \( \delta T = g(L)n \cdot v_b(x) \, dL \)) about the rotational velocity perturbations induced by the Alfven-wave modes on the last scattering surface). One can look at the modulation from another (though similar) point of view \( \delta T = g(L)n \cdot v_b(x) \, dL \). In general, vector perturbations of the metric have the form

\[ (h_{\mu\nu}) = \begin{pmatrix} 0 & B_1 \\ B_2 & H_{i,j} + H_{j,i} \end{pmatrix}, \]

where \( B \) and \( H \) are divergence-free, 3D vector fields supposed to vanish at infinity. The authors of \( \delta T = g(L)n \cdot v_b(x) \, dL \) introduced two gauge invariant quantities

\[ \sigma = \vec{H} - \vec{B} \text{ and } \vec{z}_- = \vec{v} - \vec{B} \]

which represent the vector contribution to the perturbation of the extrinsic curvature and the vorticity (cf. (6) and (13)). The general form of the CMB temperature fluctuations produced by vector perturbations is \( \delta T = g(L)n \cdot v_b(x) \, dL \)

\[ \left( \frac{\delta T}{T} \right)^{(vec)} = -Z_- \cdot n \, d\lambda + \int_{\Delta dec} \frac{\delta}{T} \cdot n \, d\lambda \]

where \( Z_- = \vec{z}_- - \vec{v} \) is a gauge-invariant generalization of the velocity field, and the subscripts \( dec \) denote the decoupling epoch \( (z_{dec} \gg 1100) \) and today respectively. We see from this equation that, besides the Doppler effect, Alfven waves gives rise to an integrated Sachs-Wolfe term. However, since the geometric perturbation \( \sigma \) decays with time, the integrated term is dominated by its lower boundary and just cancels \( \sigma \) in \( Z_- \).

The WMAP data cleaned from foreground contamination and Wiener filtered \( \delta T = g(L)n \cdot v_b(x) \, dL \) (the original temperature is given in \( \mu K \) units). Wiener filtering suppresses the noisiest modes in a map and shows the signal that is statistically significant. However, even after the cleaning and filtering some data points with the largest magnitudes seem to be suspicious. Therefore, we also made several magnitude-threshold cutoffs to check the stability of our calculations to these cutoffs.
Figure 1a shows the results of the calculations in the form suitable for the multiscaling of the type (9). The straight lines in this figure (the best fits) correspond to the multiscaling (9). The cutoff in this case excluded about 1% of the data points (we will call this data set WMAP1). Figure 1b shows analogous data with a cutoff which excluded about 10% of the data points (we will call this data set WMAP2).

Figure 2 shows the exponents \( \zeta_p \) (open circles correspond to WMAP1 data set and triangles to WMAP2) extracted from figures 1a,b as slopes of the straight lines. We also show in figure 2 as dotted line the dependence of \( \zeta_p \) on \( p \) for the Gaussian distributions (\( \zeta_p = p/4 \) for any Gaussian distribution), and we show the model dependence (7) as dashed line.

One can see that starting from \( p \approx 6 \) the data depart systematically from the Gaussian straight line and follow quite closely to the model curve (indicated by the dashed line) predicted for the Alfvén-wave dominated turbulence (7).

To give an additional support to the correspondence just noted between the WMAP data and the Alfvén wave dominated model, let us introduce a gradient measure for the cosmic microwave radiation temperature \( T \) fluctuations

\[
\chi_r = \frac{\int_{v_r} \langle \nabla T \rangle^2 \, dv}{v_r},
\]

where \( v_r \) is a subvolume with space-scale \( r \). Scaling laws of this measure, such as

\[
\frac{\langle \chi_r^p \rangle}{\langle \chi_s \rangle^p} \sim s^{-\mu_p},
\]

are an important characteristic of the temperature dissipation rate [24]. The exponents \( \mu_p \) can be related [24] to the exponents \( \zeta_p \) by the equation

\[
\mu_p = 1 - \zeta_p
\]

that allows us to check the model equation (7) also through the scaling (11) of the moments of the gradient measure.

Technically, using the cosmic microwave pixel data map, we will calculate the cosmic microwave radiation temperature gradient measure using summation over pixel sets instead of integration over subvolumes \( v_r \). The multiscaling of type (11) (if exists) will be then written as

\[
\frac{\langle \chi_s^p \rangle}{\langle \chi_s \rangle^p} \sim s^{-\mu_p}
\]

where the metric scale \( r \) is replaced by number of the pixels, \( s \), characterizing the size of the summation set. The \( \chi_s \) is a surrogate of the real 3D dissipation rate \( \chi_r \). It is believed that the surrogates can reproduce quantitative multiscaling properties of the dissipation rate [24]. Since in our calculations \( \langle \chi_s \rangle \) is independent of \( s \), we will calculate the exponents \( \mu_p \) directly from the scaling of \( \langle \chi_s^p \rangle \).

Figure 3a shows scaling of the CMB temperature gradient moments \( \langle \chi_r^p \rangle \) calculated for the WMAP1 data set against \( \ln s \). The straight lines (the best fit) are drawn to indicate the scaling in the log-log scales; b: the same as in figure 3a but for WMAP2 data set.
ing space
tations and non-Gaussian multiscaling of the correspond-
fluid turbulence (near-) Gaussianity of velocity fluctua-
Gaussian statistics [25]. Analogous situation occurs in
the previous studies of the CMB maps failed to detect
increments. We suppose that there are two reasons why
the observed multiscaling of the spectrum for the Gaussian processes is certainly in-
shown for fluid turbulence [26],[27] that knowledge about
just due to turbulence modulation). In particular, it was
responding increments of the field, which can be seen
a random field fluctuations themselves does not contra-
dict to a pronounced non-Gaussian multiscaling of cor-
responding increments of the field, which may be produced by non-linear effects due to
gravity (e.g. the Rees-Sciama effect), but the good quantitative correspondence to turbulence (both for
the structure functions and for the gradient measure),
observed in the figures 2 and 4, indicates that the
turbulence may be a dominating factor here.

sions, and to Tegmark’s group and to the NASA Goddard
Space Flight Center for providing the data.

(7),(12)).

The results presented in the paper can be considered
as a tentative indication of the existence [1]-[13] of the considerable magnetic fields at the recombination time.
The extended self-similarity (figure 2) shows clear non-
Gaussian character of the high moments which, together
with the closeness of the low moments to the Gaussian
behavior, can shad light on the longstanding discussion about Gaussianity of the small-scale cosmological fluctu-
ations. The theoretically predicted survival of the Alfvén
waves on the last scattering surface at the arcminute scales and, moreover, domination of their interactions
(the cascade collisions of the Alfvén wave packets) on
these scales can be also considered now rather plausible.
WMAP sky maps produced by the WMAP team
were analyzed by the team itself. They found the CMB
temperature fluctuations (probably\
(9)) and the fact
that non-Gaussianity does not make its appearance in
the ESS up to the 6 moment even if space increments are
considered.

Finally, it should be noted that we cannot exclude
other contributions to high-order structure functions
which may be produced by non-linear effects due to gravity (e.g. the Rees-Sciama effect), but the good
quantitative correspondence to turbulence (both for
the structure functions and for the gradient measure),
observed in the figures 2 and 4, indicates that the
turbulence may be a dominating factor here.
